Abstract

The 'sibling effect' has been widely reported in studies examining a breadth of topics in the academic literature, suggesting firstborn children are advantaged across a range of cognitive, educational and health-based measures compared with their later-born peers. Expanding on this literature using naturalistic home-recorded data and parental vocabulary report, we find that early language outcomes vary by number of siblings. Specifically, we find that children with two or more older siblings - but not one - had smaller vocabularies at 18 months, and heard less input from caregivers across several measures. We discuss implications regarding what infants experience and learn across a range of family sizes in infancy.

Keywords: Siblings, Lexical Development, Input Effects, Language Acquisition

Word count: X

20   Analysing the effect of sibling number on input and output in the first 18 months

21   Many studies assume a theoretical "optimum" environment for early language

22 development, whereby the input is tailored to a single infant's needs, changing over time as

23 language capacity develops (e.g. Soderstrom, 2007; Stern, Spieker, Barnett, & MacKain,

24 1983). However, for many infants and for many reasons, language acquisition occurs amid

25 various domestic and social factors that can influence the learning environment, including

26 the presence of older siblings in the home (Fenson et al., 1994). According to the United

27 States Census Bureau (2010), around one third of children are born into households with at

28 least one other infant present, and one in every five infants is acquiring language in a

29 household shared with two or more other children. Similar statistics are reported for British

30 infants (Office for National Statistics, 2018), where the average household has 1.75 children,

31 and 15% of households have three children or more. In this paper, we consider the role of

32 siblings in the early language environment of English-learning infants. We use naturalistic

33 home-recorded data to measure input in earlier- and later-born infants in relation to their

34 lexical development over the first 18 months of life.

35   Prior research suggests that infants born to households with older children may be

36 slower to learn language. Fenson and colleagues (1994) found that by 30 months of age,

37 children with older siblings performed worse than those with no siblings across measures of

38 productive vocabulary, use of word combinations, and mean length of utterance (MLU). This

39 'sibling effect' may be manifested in input differences between first- and later-born children:

40 some research finds that infants with older siblings hear less speech aimed specifically at

41 them, and what they do hear is understood to be linguistically less supportive of early

42 language development (Hoff-Ginsberg, 1998; Oshima-Takane & Robbins, 2003).

43 Contrastingly, some studies have noted linguistic *advantages* for later-borns, who may have

44 stronger social-communicative skills (Hoff, 2006), better understanding of pronouns

45 (Oshima-Takane, Goodz, & Derevensky, 1996), and better conversational abilities (Dunn &

Shatz, 1989). Overall, while the particulars differ across studies, prior work suggests that the presence of siblings in the home leads to differences in infants' early linguistic experience.

Numerous studies have attempted to better understand how siblings affect the language development trajectory, with comparisons of language acquisition across first- and later-borns, and analyses of mothers' input in dyadic (infant + mother) and triadic (infant + mother + older sibling) situations. Findings are mixed, but overall two general conclusions can be drawn. First, analyses consistently show that infants with older siblings generally have slower *vocabulary development* (Berglund, Eriksson, & Westerlund, 2005; Fenson et al., 1994; Pine, 1995; Zambrana, Ystrom, & Pons, 2012), but this is often marginal, and typical of the earliest stages of language learning. Hoff-Ginsberg (1998) shows first-borns to have better lexical and syntactic skills up until 2;5, but later-born infants had better conversational abilities during the same time-period. Some of these differences may relate to power to detect relatively small effects or simultaneous contributing factors. For instance, using a large longitudinal dataset of french-learning 2-5 year olds, Havron and colleagues (2019) find no effect of age gap between siblings but lower standardized language scores in children with older brothers (but not sisters) relative to those without siblings, based on parental report and direct battery assessments.

The second general finding pertains to sibling-related differences in the early linguistic *environment*: infants with no siblings receive more input overall, and this more closely reflects what is typically considered to be 'high quality' input in the extant literature. Indeed, the very presence of a sibling in the linguistic environment changes the way language is used. When siblings are present (i.e. triadic interactions), mothers' input is more focused on regulating behaviour, as opposed to the language-focused speech that is common in dyadic contexts (Oshima-Takane & Robbins, 2003). Reports show that MLU is longer in the input of first-born infants (Hoff-Ginsberg, 1998; but see also Oshima-Takane & Robbins, 2003 for a comparison of dyadic and triadic contexts), who also hear more questions directed

72 at them than later-borns. Both Jones and Adamson (1987) and Oshima-Takane and Robbins

73 (2003) report no difference between the overall number of word types produced by mothers

74 in dyadic and triadic settings, but the proportion of speech directed at the target infant is

75 drastically reduced when input is shared with siblings.

76 As Hoff (2006) explains, infants with siblings have less experience of speech directed at

77 them, but they do have an advantage over their first-born peers in that they are subject to

78 more overheard speech. Indeed, the input of first-borns may be explicitly tailored to their

79 needs, but equally this means it might be less varied. Barton and Tomasello (1991) show

80 that by as early as 19 months, infants with siblings are already able to take part in triadic

81 conversations, which were almost three times longer than dyadic conversations. The authors

82 suggest that the presence of siblings may shift the learning context, and facilitate infants'

83 participation in communicative interactions: infants are under less pressure to participate in

84 a triadic interaction, meaning the conversation can continue even when the infant is unable

85 to respond. As a result, the infants in Barton and Tomasello's study took more

86 conversational turns in triadic interactions than dyadic ones.

87 There thus may be a trade-off in development between highly supportive one-to-one

88 input from a caregiver (cf. Ramírez-Esparza, García-Sierra, & Kuhl, 2014) and the potential

89 benefits drawn from communicating with a sibling.

90 In the present study, we test the extent to which having more versus fewer siblings in

91 the home environment may lead to differences in vocabulary development and the early

92 linguistic environment over the course of the first 18 months of life.

93 In analyzing infants' lexical development in relation to the presence of older siblings in

94 their household, the present work expands on the extant literature in two key ways. First,

95 prior work generally considered birth order as a binomial factor (i.e. comparing first-born

96 infants with second-borns (e.g. Oshima-Takane & Robbins, 2003), or 'later-borns' (e.g.

97 Hoff-Ginsberg, 1998), potentially missing graded effects. Instead of this approach, we

consider the number of siblings, i.e. how having *more versus fewer siblings* is linked to an infant's lexical development and their early linguistic environment. Second, much of the existing literature in this area is drawn from questionnaire data or brief interactions recorded in the lab (but see Dunn & Shatz, 1989 for a study of naturalistic home-recorded data), rather than naturalistic day-to-day interactions in the home. In contrast, we analyze an existing corpus of daylong audio- and hour-long video-recordings in concert with vocabulary checklists. Based on work summarized above, we expect that both the language environment and infants' early vocabulary will vary as a function of how many older siblings they have.

Hypotheses

Research has already shown that early lexical development is more advanced among first-born infants (e.g. Hoff-Ginsberg, 1998). We expect to see the same effect in our data, but we hypothesize that the closer granularity of this analysis will show a gradient decline in infants' lexical abilities in relation to an increasing number of siblings. With regard to the infants' linguistic environment, we hypothesize that increased sibling number will have a negative effect on factors of the early input that are known to support language development. To test this, we adopt three input measures, established in the literature as being important for early language learning. The measures and our specific predictions are as follows:

1) **Amount of input** will be lower for children with more siblings. Caregivers' attention will be divided across a larger group of children, and as a result the proportion of input from the mother will be lower for infants with more siblings. In addition, these infants will experience more input from other children in the home. Amount of overall input is an important predictor of language development in the longer term (Huttenlocher, Haight, Bryk, Seltzer, & Lyons, 1991), as is amount of one-to-one input from the caregiver (Ramírez-Esparza et al., 2014), while overall speech in the environment (i.e. including speech not necessarily directed at the infant) does not appear to support

123   lexical development (*ibid*). We thus expect amount of input directed towards the child

124   to be an important determiner of infants' lexical production skills at 18 months.

125   2) **More 'learnable' words** (words that tend to be acquired earlier, Fenson et al., 1994)

126   will occur in the input of infants with fewer siblings than the input of those with more

127   siblings. This prediction stems from the idea that input from older children will

128   generate a wider variety of lexical items in the input, including words directed to and

129   produced by siblings, some of whom will still be young language learners themselves.

130   As a result, in homes with older siblings, we predict that the lexical items in the input

131   will be less typical of words acquired earlier on in development.

132   3) **Amount of object presence** (word + object co-occurrence, e.g. mother says 'cat'

133   when there is a cat in the room) will decrease as sibling number increases. This

134   predictions stems from the idea that as caregivers' attention is drawn away from

135   one-to-one interactions with the infant, there will be less opportunity for contingent

136   talk. Moreover, less "learnable" words are also expected to be less imageable, and thus

137   less likely to be presented alongside caregivers' utterances. The co-occurrence of words

138   alongside their referents is thought to contribute to the earlier learning of nouns over

139   verbs (E. Bergelson & Swingley, 2013), as it supports the word learning process

140   through the concrete mapping of word to referent (Gleitman, Cassidy, Nappa,

141   Papafragou, & Trueswell, 2005). Furthermore, object presence is more suited to

142   instances of joint visual attention with the caregiver, which is less likely to occur in

143   households where caregiver attention is shared between multiple children.

Methods

144

145   We analyze data from the SEEDLingS corpus (Elika Bergelson, Amatuni, Dailey,

146   Koorathota, & Tor, 2019), a longitudinal set of data incorporating home recordings, parental

147   reports and experimental studies from the ages of 0;6 to 1;6. The present study draws on the

parental report data, and annotations of hour-long home video recordings, taken on a monthly basis during data collection. We also ran our analysis using day-long audio recordings taken on a different day from the video data reported below; unless reported otherwise, all results were consistent with those outlined below (see Supplementary Materials).

Participants

Forty-four families in New York State completed the year-long study. Infants (21 females) were from largely middle-class households; 33 mothers had attained a B.A. degree or higher. All infants had normal birthweight with no reported speech- or hearing-relevant diagnoses. Forty-two infants were Caucasian; two were from multi-racial backgrounds.

Materials

Parental report data We draw on data from vocabulary checklists [Macarthur-Bates Communicative Development Inventory, hereafter CDI; Fenson et al. (1994)], administered monthly from 0;6 to 1;6, along with a demographics questionnaire. Because the majority of infants did not produce their first word until around 0;11 according to CDI reports (M=10.70, SD=2.22)[1], we use CDI data from 0;10 onwards in our analysis. CDI production data for each month is taken as a measure of the infants' lexical development over the course of the analysis period. Supplementing this parental report, we also consider words produced in the hour-long video- and day-long audio-recordings.

Home-recorded video and audio data Every month between 0;6 and 1;5, infants

---

[1]Note that reported word production began earlier than observed word production (i.e. in the video recordings) but this difference was not statistically significant (see Moore, Dailey, Garrison, Amatuni, & Bergelson, 2019).

were video-recorded for one hour in their home, capturing a naturalistic representation of each infant's day-to-day input. Infants wore a hat with two small Looxcie video cameras attached, one pointed slightly up, and one pointed slightly down; this allowed us to record the scene from the infants' perspective. In the event that infants refused to wear the hats, caregivers wore the same kind of camera on a headband. Additionally, a camcorder was set up in the home. On a different day in the same month, the infants were recorded for upto 16 hours using a LENA recorder (*LENA Research Foundation*, 2018) hidden in a small vest worn by the infant. Object words (i.e. concrete nouns) deemed to be directed to or attended by the child were annotated by trained coders. Here we examine annotations for speaker, i.e. who produced a word, and object presence, i.e. whether the word's referent was present and attended to by the infant.

Procedure

We analyzed number of siblings based on parental report in the demographics questionnaires completed at 0;6 (R: 0-4). Siblings were on average 4.05 years older than the infants in this study (Mdn days: 1477, SD: 1477, R: 0-17 years).[2] All siblings lived in the household with the infant, and all were older than or of the same age as the infant in question.[3] ## Input measures

Three input measures were derived based on the annotations of concrete nouns in this corpus, each pertaining to aspects of the input that are established as important in early language learning: **overall household input** (how many concrete nouns does each infant hear?), **early-acquired words** (how much of this input is *early-learned* nouns?), and **object presence** (how much of this input is referentially transparent?). Each is described

---

[2]For six infants, siblings' exact birthdates were not provided, and so age difference was estimated by subtracting the infant's age (6 months) from the sibling's age in years, as listed on the questionnaire (e.g. if a sibling was 5 years old, they were classed as being 4.5 years older than the infant).

[3]Two infants in the dataset were dizygotic twins; our pattern of results holds with or without these infants.

in further detail below.

Household Input reflects how many nouns infants heard in the recordings from their mother, father and (where relevant) siblings. Other speakers' input was relatively rare during video recordings, accounting for 11.42% of input overall (SD=22.82%), and is excluded from our analysis. This measure of the early language environment is based on evidence showing strong links between the amount of speech heard in the early input and later vocabulary size (Anderson, Graham, Prime, Jenkins, & Madigan, 2021). This analysis considers only nouns produced by speakers in the child's environment; concrete nouns are acquired earlier in development in English and cross-linguistically (Braginsky, Yurovsky, Marchman, & Frank, 2019), and for this corpus of data, noun prod correlates strongly with automated adult word count estimates (Bulgarelli & Bergelson, 2020). Higher noun count in this data thus indicates higher input across the board.

Early-acquired words reflects the proportion of object word lemmas in the parental input that appeared on the "Words & Gestures" communicative development inventory (CDI, Fenson et al., 1994). The CDI items were established based on a sample of over 1,700 infants (~50% firstborn, 73% White, 44% of mothers with a college diploma), and so the CDI is taken as a standardized proxy of words typically acquired by infants in early development. Frank and colleagues (2021) show that the earliest-learned words are very similar across languages, suggesting a conceptual bias towards some words over others in early acquisition (though many factors, e.g. frequency, concreteness, phonological complexity, are relevant as well).

Object Presence was coded for each object word in the home recordings based on whether or not the annotator determined the object in question as present and attended to by the child. This is a metric of referential transparency, which has been suggested to aid in learning (E. Bergelson & Swingley, 2013). Bergelson and Aslin (2017) found that word-object co-presence in the home correlated with infants' ability to recognise the same

²¹⁶ words in an eye-tracking experiment, suggesting an advantage for object labeling in word

²¹⁷ learning. This is consistent with findings from Cartmill and colleagues (2013), who found

²¹⁸ that more referentially-transparent interactions with the caregiver (as judged by adult

²¹⁹ speakers observing videos where target words were blanked out) predicted larger vocabulary

²²⁰ size at 54 months. Indeed, presence of the labelled object decreases the ambiguity of the

²²¹ learning environment (Yurovsky, Smith, & Yu, 2013), and may be a crucial component of

²²² supportive contingent talk (McGillion, Pine, Herbert, & Matthews, 2017).

²²³   In the following analyses, we consider infants' productive vocabulary alongside our

²²⁴ three input measures: amount of household input, number of early-acquired nouns in the

²²⁵ input, and extent of object presence in the input, as a function of sibling number. These

²²⁶ measures index both input quality and quantity (though we make no distinction between

²²⁷ quality/quantity of input here), and will be analysed in relation to infants' productive

²²⁸ vocabulary (all word types included) as our dependent measure. Since the raw data are

²²⁹ highly skewed, log-transformed data[4] and/or proportions are used for statistical analysis. All

²³⁰ figures display non-transformed data for interpretive ease.

Results

²³²   Vocabulary development was highly variable across the 44 infants. By 18 months, 2

²³³ infants produced no words, while mean productive vocabulary was 60.28 words (SD=78.31,

²³⁴ Mdn=30.50). One female infant had a substantially larger reported vocabulary (3SDs above

²³⁵ the mean monthly vocabulary score) between 1;1 and 1;6 and was classed as an outlier. We

²³⁶ removed her from our data, leaving 43 infants (20 females) in the present analysis. Infants

²³⁷ had one sibling on average (M=0.86, Mdn=1, SD=1.09). See Table 1.

---

[4]1 was added to the raw infant production data of all infants before log-transformation to retain infants
with vocabularies of 0.

Table 1

Sibling number by female and male infants.

n Siblings	Female	Male	Total
0	9	12	21
1	7	6	13
2	2	3	5
3	2	0	2
4	0	2	2
Total	20	23	43

Model structure for fixed and random effects

All reported models were generated in R (R Core Team, 2019) using the *lmerTest* package to run linear mixed-effects regression models (Kuznetsova, Brockhoff, & Christensen, 2017). P-values were generated by likelihood ratio tests resulting from nested model comparison. All models include infant as a random effect. All post-hoc tests are two-sample, two-tailed Wilcoxon Tests; given that all but one of our variables differed significantly from normal by Shapiro tests, we opted to run non-parametric tests for all post-hoc comparisons. Where multiple post-hoc comparisons are run on the same dataset, Bonferroni corrections are applied with an adjusted threshold of a=0.02, accounting for two between-group comparisons (no siblings vs. one sibling, one sibling vs. multiple siblings; see below).

Before considering sibling status, we first modelled infants' productive vocabulary at 18 months (taken from CDI questionnaires) as a function of age, sex, and mother's education. There was no effect of sex (p=.632), and no correlation with mothers' education level (across five categories from High School to Doctorate; r = -0.01, p=.139). As expected, age had a

252 significant effect on productive vocabulary ($p<$ .001), and so we include age as a fixed effect

253 in all subsequent models. Because we expected that maternal age and education might have

254 an effect on both sibling number and infant productive vocabulary, we ran further

255 correlations to test these variables. There was no correlation between mother's education

256 and number of siblings ($r =$ -0.01, p=.928), and a marginal positive correlation between

257 mother's age and number of siblings (Spearman's $r =$ 0.28, p=.069); older mothers tended to

258 have more children. However, no correlation was found between mothers' age and productive

259 vocabulary at 18 months ($r =$ -0.04, p=.822).

260 **Effect of siblings on infants' productive vocabulary**

261   We next modeled the effect of siblings on productive vocabulary. We tested three

262 vocabulary measures (CDI questionnaires, video data and day-long audio recordings), as well

263 as three variables representing the sibling effect: a binary variable (0 vs. >0 siblings),

264 aggregated groups (None vs. One vs. 2+), and discrete sibling number (0 vs. 1 vs. 2 vs. 3

265 vs. 4 siblings). Outcomes from model comparisons are shown in Table 2. Across the data,

266 the simple fact of having siblings (i.e. as a binary variable) did not affect productive

267 vocabulary. Discrete sibling number predicted reported CDI vocabulary and number of word

268 types (but not tokens) produced in the video data; this was marginally significant in the

269 audio data. Sibling group predicted vocabulary size in the CDI measures but not in the

270 audio or video data (again this was marginally significant in the video data).

Table 2

Output from regression models comparing language development over time in relation to

sibling number (binary, grouped and discrete variables). Month was included in each model as

a fixed effect; subject was included as a random effect.

Count	Model	Data	Df	Chisq	p value
CDI	0 vs. >0 siblings	CDI	1	2.27	0.13

	Sibling group	CDI	2	7.96	0.02
	Sibling number	CDI	1	6.24	0.01
Tokens	0 vs. >0 siblings	Video	1	1.50	0.22
	0 vs. >0 siblings	Audio	1	0.57	0.45
	Sibling group	Video	2	2.72	0.26
	Sibling group	Audio	2	0.73	0.69
	Sibling number	Video	1	3.06	0.08
	Sibling number	Audio	1	1.24	0.27
Types	0 vs. >0 siblings	Video	1	3.74	0.05
	0 vs. >0 siblings	Audio	1	2.10	0.15
	Sibling group	Video	2	5.71	0.06
	Sibling group	Audio	2	3.42	0.18
	Sibling number	Video	1	5.87	0.02
	Sibling number	Audio	1	3.65	0.06

Having more siblings was associated with a smaller vocabulary size over the course of early development. This is consistent with previous findings (Hoff-Ginsberg, 1998; Pine, 1995). Moreover, for each additional sibling, infants were reported to have acquired 31% fewer words, and produced 14% fewer words in the hour-long video recordings. The 'sibling effect' is thus present in our data, though this is manifested differently across our different data types: CDI and video data reveal an effect for siblings on productive vocabulary, but not audio data. We opted to draw on the reported CDI vocabulary scores as our key measure of productive vocabulary, which we take as more representative of the infants' vocabulary size as a whole (cf. Moore et al., 2019). The grouped sibling variable (0 vs. 1 vs. 2+) was selected as our measure of siblings as it allows analysis across more equal group sizes. However, note that all results reported below were consistent when discrete sibling

282 number was analysed, unless reported otherwise.

283   According to CDI reports, infants with one sibling acquire only 5% fewer words than

284 firstborns over the course of our analysis, while infants with two or more siblings produce

285 94% fewer words. See Table 3 and Figure 1. Post-hoc Wilcoxon Rank Sum tests comparing

286 reported productive vocabulary at 18 months revealed significantly larger vocabularies for

287 infants with one sibling compared to those with two or more siblings (W=5, $p = .004$), but

288 no difference between infants with one sibling and those with no siblings (W=79.50, $p =$

289 $.631$; Bonferroni corrections applied).

Effect of siblings on infants' input

291   Having established that infants' productive vocabulary varied as a function of how

292 many siblings they had, we turn to our three input measures to test whether input varied by

293 a child's sibling status. To keep relatively similar Ns across groups we used the 0 vs. 1 vs. 2+

294 siblings division. That said, with the exception of household input (see Supplementary Data)

295 all reported model outcomes hold if we model discrete sibling number as a fixed effect

296 instead.

297   As with our previous analysis, we first modeled infants' input (maternal input only) as

298 a function of age, sex and maternal education. This time, there was no effect for age, nor sex

299 or maternal education (ps all>.260) on the amount of input produced by mothers. We

300 therefore excluded all three variables from our models.

301   **Parental Input.**   Mothers provided the largest proportion of the infants' overall

302 input across the sample (80%, M=146.10 object words, Mdn=125, SD=119.97). Fathers

303 accounted for an average of 14% (M=22.13, Mdn=0, SD=48.31), while infants with siblings

304 received around 6% of their input from their brothers and sisters (M=16.18, Mdn=11,

305 SD=18.51). See Table 3 and Figure 2. We tested overall quantity of input (aggregated across

Figure 1. Reported productive vocabulary acquisition (CDI) over time. Colors denote sibling group; line with grey confidence band reflects local estimator (loess) fit over individual infants' vocabulary at each month. Triangles indicate mean with bootstrapped CIs computed over each month's data. Points (jittered horizontally) show individual infants' vocabulary size at each month. Y-axis utilizes log-transformed vertical spacing for visual clarity.

306 mothers, fathers, and siblings) in our model, and a significant effect was found ($\chi^2(2) =$

307 18.48, $p<$ .001). We then ran post-hoc tests to compare mean amount of input across sibling

308 groups. With Bonferroni corrections applied (a=0.02), these showed a significant difference

309 in average input received between infants with one sibling versus those with two or more

310 siblings (W=7, $p<$ .001) while amount of input did not differ between infants with no

311 siblings and those with one sibling (W=120, $p =$ .576). On average, in any given hour-long

312 recording, infants with no siblings heard -4 more object words in their input than those with

313 one sibling, and 89 more than those with two or more siblings. Infants with one sibling heard

Table 3

Data summary of all three input variables and reported vocabulary size at 18 months.

Variable	No siblings		1 sibling		2+ siblings	
	none m	none sd	1 m	1 sd	2 m	2 sd
% early-acquired words in input	0.64	0.13	0.61	0.13	0.62	0.14
% object presence in input	0.67	0.15	0.56	0.15	0.46	0.18
N Input utterances, 10-17 months	180.63	124.68	184.43	84.59	100.19	52.64
Productive Vocabulary 18m (CDI)	58.89	60.76	92.64	111.42	13.00	9.49

314 94 more object words than those with two or more siblings.

315   Next, we tested how much of that input came from siblings (for infants who had them).
316 Overall, for infants who had siblings, at least one other child was present in 72.16% of
317 recordings (n = 176). Wilcoxon Rank Sum tests showed no difference between the amount of
318 sibling input received by infants with one sibling compared with those with two or more
319 siblings (W=40, p=.235, Bonferroni corrections applied), contrasting with predictions set
320 out in our first hypothesis. Looking at caregivers individually, infants with two or more
321 siblings heard significantly less input from their mothers than those with one sibling (W=15,
322 p=.003), while there was no difference between those with one vs. no siblings (W=126, $p =$
323 .727). Finally, amount of paternal input did not differ between groups (one vs. none:
324 W=152, $p = .606$; one vs. 2+: W=42, p=.296).

325 **Early-acquired words.**   We expected infants with more siblings to hear fewer
326 early-acquired words (i.e. fewer words that occur on the CDI). We consider proportion of
327 early-acquired words from all of the input words included in the analysis above in order to
328 account for differences in amount of input by sibling group. On average, 62% of the object
329 words heard in the infants' inputs were included on the CDI (Mdn=0.63, SD=0.11). However,
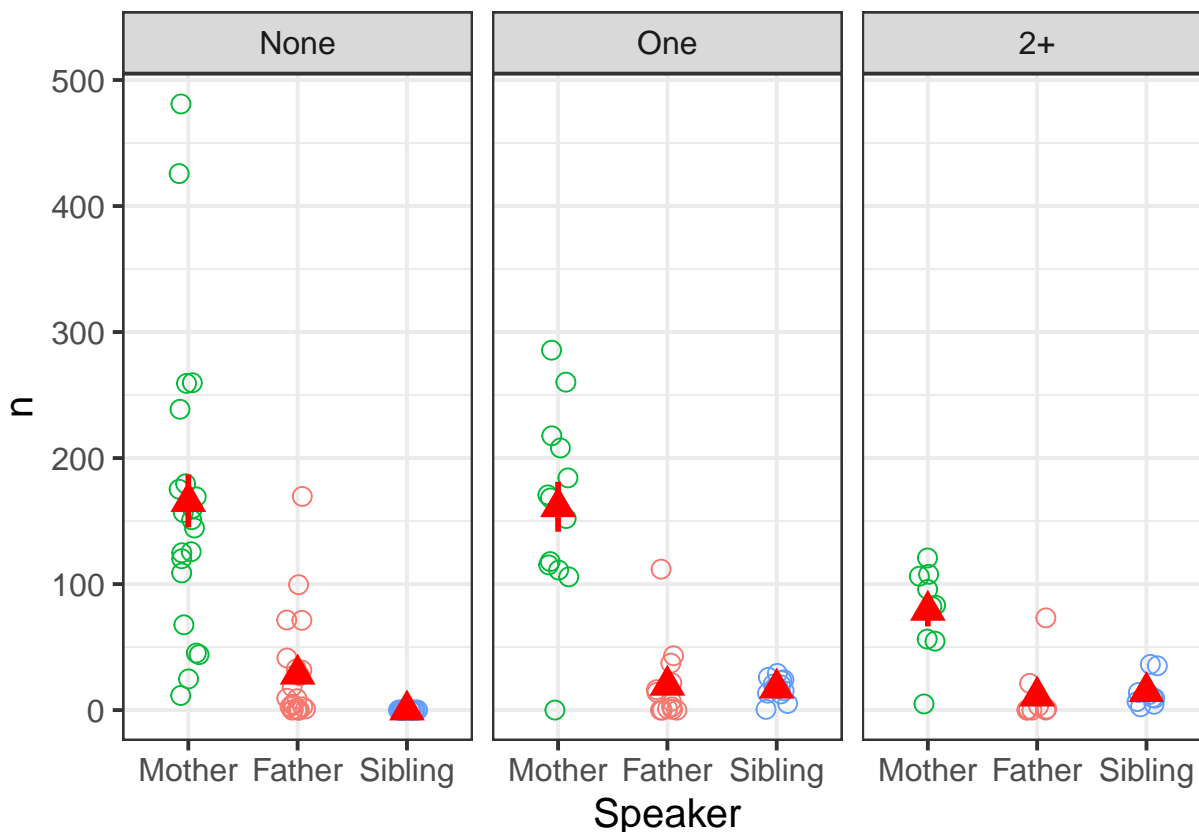

Figure 2. Mean number of words produced by Mothers, Fathers and Siblings across sessions recorded between 10-17 months. Circles represent values for individual infants; red triangles show group means.

330   this did not vary by sibling group ($\chi^2(2) = 2.90$, *p*=.234). See Table 3 and Figure 3).

331   **Object presence.** On average, 60% of utterances were produced in the presence of

332   the relevant object (Mdn=0.60, SD=0.12). We hypothesized that infants with more siblings

333   would hear fewer words in referentially transparent conditions (i.e. they would experience

334   lower object presence) than those with fewer siblings. Indeed, modelling the quantity of

335   object present tokens that infants heard, we find a significant effect for sibling group on

336   object presence ($\chi^2(2) = 26.09$, *p*< .001). See Figure 4. Infants with no siblings experienced

337   23% more object presence in their input than those with two or more siblings, and 12% more

338   than those with one sibling. Post-hoc comparisons revealed significant between-group
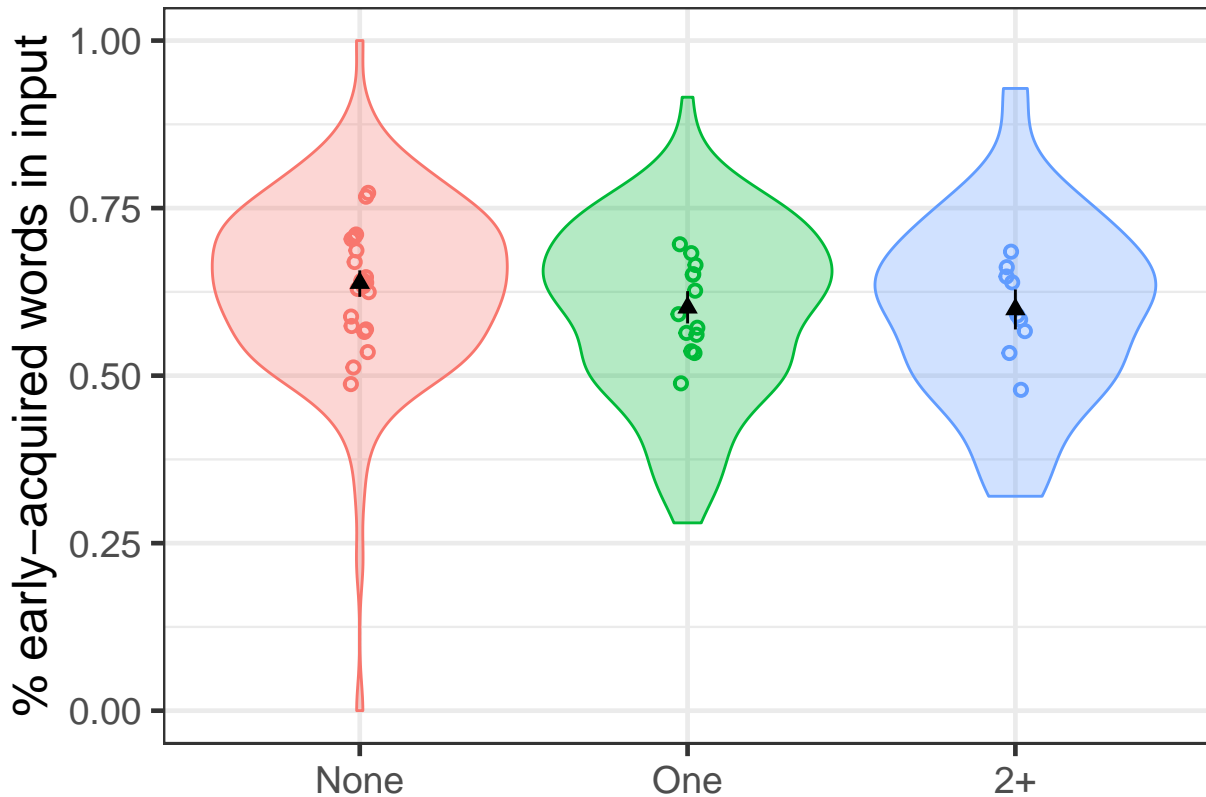

Figure 3. Proportion of early-acquired words in the input, across sibling groups. Error bars indicate mean learnable words heard across groups, with bootstrapped 95% CIs computed over all data. Dots indicate mean number of early-acquired words per infant, collapsed across age and jittered horizontally for visual clarity.

339 differences: infants with no siblings experienced significantly more object presence than those

340 with one sibling (W=234, $p<$ .001, Bonferroni corrections applied). Likewise, infants with

341 one sibling experienced significantly more object presence those with two or more siblings

342 (W=20, p=.009). See Table 3.

343   **Discussion**

344   We investigated the nature of infant language development in relation to number of

345 children in the household. Previous research found a delay in lexical acquisition for

346 later-born infants (Fenson et al., 1994; Hoff, 2006), with differences in input across birth
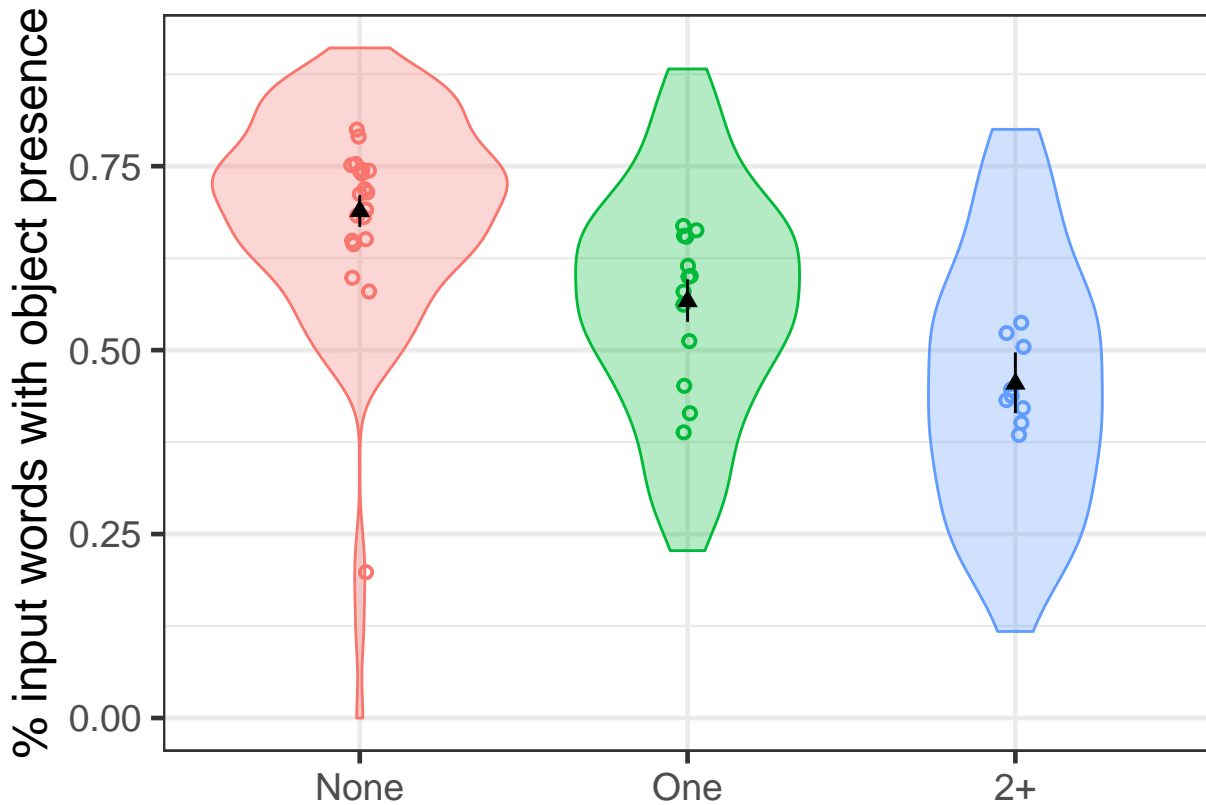

Figure 4. Proportion of input words produced with object presence in the input across sibling groups. Error bars and black triangles show 95% CIs and mean proportion of object presence across sibling groups. Dots indicate mean proportion of object presence per infant, collapsing across age and jittered horizontally for visual clarity.

order reported as a root cause. Our results add several new dimensions to this, by testing for differences across more vs. fewer older siblings, and by looking at input during child-centered home recordings. Infants with more siblings were reported to say fewer words by 18 months, heard fewer nouns from their parents and siblings, and experienced less 'object co-presence' when hearing them. However, controlling for amount of input, all groups heard around the same proportion of typically early-acquired words.

Importantly, and in contrast with some previous research (Hoff-Ginsberg, 1998; Oshima-Takane & Robbins, 2003), infants with one sibling showed no delay in lexical production and minimal reduction in input in comparison to first-born infants. That is, our

356 results suggest that simply having a sibling does not contribute to input or vocabulary

357 differences across children (as measured here), while having more than one siblings seems to

358 do so. Indeed, infants with zero and one sibling had similar results for productive vocabulary,

359 parental noun input overall, and early-acquired nouns in the input (but not object presence,

360 which we return to below). In contrast, infants with two or more siblings said fewer words,

361 and also heard fewer input words with proportionally less object co-presence, compared with

362 their peers.

363   When we considered the effect of sibling status – that is, whether or not infants had

364 any siblings, disregarding specific sibling number – our findings showed that having siblings

365 made no difference to infants' lexical production capacities. This contrasts with

366 Hoff-Ginsberg (1998), who found that, by 18 months, laterborns exhibit lower language skills.

367 However, Oshima-Takane and colleagues (1996) found no overall differences between first-

368 and second-born children across a range of language measures taken at 21 months. Our

369 finer-grained results suggest a greater role for *sibling quantity* over first- vs. later-born status.

370 The more older siblings a child had, the lower their reported productive vocabulary at 18

371 months. This adds to findings from Fenson and colleagues (1994), who found a weak but

372 significant negative correlation between birth order and production of both words and

373 gestures. Controlling for age, our model showed that for each additional older sibling, infants

374 produced more than 30% fewer words by 18 months. While infants with more siblings heard

375 less input speech overall, having one sibling did not significantly reduce the number of nouns

376 in an infant's input. This is in direct contrast with reports from the literature; Hoff (2006)

377 states that "when a sibling is present, each child receives less speech directed solely at. . . her

378 *because mothers produce the same amount of speech whether interacting with one or two*

379 *children*" (p.67, italics added). While this does not appear to be the case in the present

380 dataset, it may be due to the circumstances of the home-recorded data: while siblings were

381 present in many of the recordings (72.16% of recordings in which the target child had a

382 sibling), given the focus of the data collection, parents may have had a tendency to direct

their attention - and consequently their linguistic input - more towards the target child. Alternatively, our results may diverge from those of Hoff (2006) due to the nature of our input measure, which only took nouns into account. However, Bulgarelli and Bergelson (2020) show that nouns are a reliable proxy for overall input in this dataset, thus suggesting that this measure provides an appropriate representation of overall input directed at the target child.

Moreover, infants with siblings did not hear much speech from their older brothers and sisters. This is contrary to our hypothesis, as having more siblings did not predict more sibling input. Similar findings are reported in a lab-based interaction study by Oshima-Takane and Robbins (2003), who found that older siblings rarely talked directly to the target child; instead, most input from siblings was overheard speech from sibling-mother interactions. However, results from Havron and colleagues (2019) indirectly suggest that speech from siblings may affect language development, and not necessarily in a negative direction. They found that children with older brothers had lower verbal skills than children with no siblings; children with older sisters did not show this effect. The authors propose that this differential effect could be due sisters having positive effects on language development (i.e., the effect is derived from supportive sibling input), or perhaps due to brothers' additional demands on caregiver time and attention, thus directing caregiver attention away from the target child (i.e., the effect is derived from changes to caregiver input). We did not analyse sibling sex in our data, but future analyses could consider input speech in relation to sibling sex.

The 'sibling effect' was most marked in our analysis of object presence. In this case, even having one sibling led to fewer word-object pairs presented in the input. Presence of a labeled object with congruent input speech is known to be supportive in early word learning: Bergelson and Aslin (2017) combined analysis of this home-recorded data with an experimental study to show that word-object co-presence in naturalistic caregiver input

supported comprehension of nouns when tested using eye-tracking. Gogate and colleagues (2000) state that contingent word production supports the learning of novel word-object combinations, as "multimodal motherese" - whereby a target word is produced in synchrony with its referent, often involving movement or touch of the object - supports word learning by demonstrating novel word-object combinations. Indeed, lower rates of referential transparency in children's input have also been proposed to explain why common non-nouns like *hi* and *uh-oh* are learned later than concrete nouns (E. Bergelson & Swingley, 2013).

The one measure that did not generate any kind of sibling effect was infants' exposure to early-acquired (CDI) words; infants heard roughly the same proportion of CDI nouns in the input regardless of how many siblings they had. This may be due to limitations of our analysis, which take into account only nouns, accounting for 224 word types in total. This may not be enough to account for input differences between groups. Alternatively, proportion of CDI nouns may not have differed because when speech was directed at the infant, the nouns produced by the caregiver were those we would expect in speech directed at a baby. As reported above, input from siblings was low overall, and so perhaps unlikely to affect the lexical characteristics of the input.

Object presence varied more linearly across sibling quantity, suggesting it may be a less critical driver of early word production. Given that infants with one sibling heard approximately the same number of object words in the input than those with no siblings, this may be the most crucial factor in predicting a child's vocabulary size by 18 months. Alternatively, the reduced object presence for children with one sibling may have been compensated for in other ways we did not measure here, which in turn resulted in the indistinguishable vocabulary difference in the 0 and 1 sibling children at 18 months.

More generally, one possibility raised by these results is that perhaps parents are able to compensate or provide relatively similar input and learning support for one or two children, but once children outnumber parents, this balancing act of attention, care, and

time, becomes unwieldy. While the current sample is relatively limited and homogenous in the family structures and demographics it includes, future work could fruitfully investigate this possibility by considering whether (controlling for other potential contributors like SES, Hoff-Ginsberg, 1998) the presence of more caregivers (whether parents, relatives, or other adults) helps foster language development.

Alternatively, second-borns might 'even out' with children with no siblings due to a trade-off between direct attention from the caregiver and the possibility of more sophisticated social-communicative interactions. For these infants there is still ample opportunity to engage with the mother in one-to-one interactions, allowing a higher share of her attention than is available to third- or later-borns. Furthermore, triadic interactions can benefit the development of a number of linguistic and communication skills (Barton & Tomasello, 1991; Dunn & Shatz, 1989). Second-borns may also benefit from overheard speech in their input, supporting the acquisition of nouns and even more complex lexical categories (Floor & Akhtar, 2006; Oshima-Takane et al., 1996). For infants with one sibling, the benefits of observing/overhearing interactions between sibling and caregiver, as well as the possibility for partaking in such interactions, may outweigh the decrease in some aspects of the input (i.e., in our data, only observed in object presence). Having more than one sibling may throw this off-balance.

Importantly, the present results make no claims about eventual outcomes for these children: generally speaking, regardless of sibling number, all typically-developing infants reach full and fluent language use. Indeed, some research suggests that sibling effects, while they may be clear in early development, are not always sustained into childhood; e.g. twins are known to experience a delay in language development into the third year, but are quick to catch up thereafter (Dales, 1969; Tomasello, Mannle, & Kruger, 1986). This demonstrates the cognitive adaptability of early development, which brings about the acquisition of language across varying and allegedly 'imperfect' learning environments. Infants' capacity to

develop linguistic skills from the resources that are available to them – whether that is infant-directed object labels or overheard abstract concepts – highlights the dynamic and adaptable nature of early cognitive development, and a system that is sufficiently robust to bring about the same outcome across populations.

Of course, the 'success' of early language development is defined by how success is measured. Here we chose word production as our measure of linguistic capability; we did not consider other equally valid measures such as language comprehension or early social-interaction skills. Similarly, our input measures focused on nouns; other lexical classes may reveal different effects, though they are generally sparser until toddlerhood. There is also some imbalance in group sizes across our data; our sample was not pre-selected for sibling number, and so group sizes are unmatched across the analysis. Including a larger number of infants with 2+ siblings may have revealed a different pattern of results. Finally, more work across wider and larger populations is necessary to unpack the generalizability of the present results. Our sample is refelective of average household sizes in middle-class families across North America and Western Europe (Office for National Statistics, 2018; United States Census Bureau, 2010), but it is not unusual in some communities and parts of the world for households to include between three and six children on average (Institute for Family Studies & Wheatley Institution, 2019). Adding to this, it is also necessary to consider cross-cultural differences in the way children are addressed by their parents. Casillas, Brown and Levinson (2019) found that almost all of Tseltal Mayan children's input came from speech directed at other people (21 minutes per hour, compared with just under 4 minutes/hour of specifically child-directed input), while Shneidman and Goldin-Meadow (2012) found that 69% of speech directed at Mayan children came from siblings (in comparison with 10% for children in the USA).

In conclusion, our results support the general findings from the literature showing that later-born infants have slower lexical acquisition than their first-born peers. However, we

highlight an important difference from previous findings, namely that in the present sample, second-born infants show no such effect, while infants with more than two siblings have significantly smaller vocabularies at age 18 months. We related this directly to the infants' input over a period of one year. Future studies should consider the granularity of more versus fewer siblings, and how this relates to language abilities over the course of development.
